Cobalt-, zinc-, and nickel-zinc-substituted nano-size manganese ferrite powders, MnFe₂O₄, Mn₀₈Co₀₂Fe₂O₄, Mn₀₈Zn₀₂Fe₂O₄ and Mn₀₈Ni₀₂Zn₀₂Fe₂O₄, were fabricated using a sol-gel method, and their crystallographic and magnetic properties were subsequently studied. The MnFe₂O₄ ferrite powder annealed at temperatures above 523 K exhibited a spinel structure, and the particle size increased as the annealing temperature increased. All ferrites annealed at 773 K showed a single spinel structure, and the lattice constants and particle size decreased with the substitution of Co, Zn, and Ni-Zn. The Mössbauer spectrum of the MnFe₂O₄ ferrite powder annealed at 523 K only showed a doublet due to its superparamagnetic phase, and the Mössbauer spectra of the MnFe₂O₄, Mn₀₈Co₀₂Fe₂O₄, and Mn₀₈Zn₀₂Fe₂O₄ ferrite powders annealed at 773 K could be fitted as the superposition of two Zeeman sextets due to the tetrahedral and octahedral sites of the Fe³⁺ ions. However, the Mössbauer spectrum of the Mn₀₈Zn₀₂Fe₂O₄ ferrite powder annealed at 773 K consisted of two Zeeman sextets and one quadrupole doublet due to its ferrimagnetic and paramagnetic behavior. The area ratio of the Mössbauer spectra could be used to determine the cation distribution equation, and we also explained the variation in the Mössbauer parameters by using this cation distribution equation, the superexchange interaction and the particle size. Relative to pure MnFe₂O₄, the saturation magnetizations and coercivities were larger in Mn₀₈Co₀₂Fe₂O₄ and smaller in Mn₀₈Zn₀₂Fe₂O₄ and Mn₀₈Ni₀₂Zn₀₂Fe₂O₄. These variations could be explained using the site distribution equations, particle sizes and magnetic moments of the substituted ions.

Keywords: substituted manganese ferrite, sol-gel method, Mössbauer spectroscopy, saturation magnetization, coercivity

1. Introduction

Ferrites are important materials because they are relatively inert and their properties can be tailored via chemical manipulations. Ferrites have a spinel crystal structure (space group Fd3m) in which the O²⁻ ion lattice forms areas with tetrahedral and octahedral local symmetry, and these are respectively referred to as A and B sites in the spinel formula AB₂O₄. For example, manganese ferrite, MnFe₂O₄, has a spinel crystal structure and has been used extensively in microwave and magnetic recording applications. In a normal spinel structure, divalent ions (Mn²⁺) only occupy the A sites, and trivalent ions (Fe³⁺) only occupy the B sites. In an inverse spinel structure, divalent ions occupy half of the B sites, and trivalent ions occupy the rest of the B sites and all A sites. In MnFe₂O₄ prepared at high temperatures (> 1,173 K), 20 % of the Mn²⁺ ions migrate from the A to B sites, which means that MnFe₂O₄ may be characterized as a mixture of normal and inverse spinel ferrite [1-3]. Cobalt ferrite, CoFe₂O₄, has a cubic spinel structure and has been extensively studied due to its interesting magnetic properties. Cobalt ferrite is basically an inverse spinel for which the corrected cation distribution becomes (Co₀₁Fe₀₉₀)[Co₀₈Fe₁₁]O₄. The degree of inversion thus depends on its thermal history. Cobalt ferrite has been regarded as a competitive alternative for high-density magnetic recording media due to its high coercivity.
moderate saturation magnetization, remarkable chemical stability, and mechanical hardness [4, 5]. Zinc ferrite, ZnFe$_2$O$_4$, has a normal spinel structure, where the diamagnetic Zn$^{2+}$ ions occupy only A sites, and as a result, all Fe$^{3+}$ ions are in B sites and are coupled between each other via superexchange pathways through A sites. The B-B interactions are very weak, and normal spinel ZnFe$_2$O$_4$ shows long-range antiferromagnetic ordering at $T_N = 9-11$ K. Nickel ferrite, NiFe$_2$O$_4$, has an inverse spinel structure in which the A sites are occupied by Fe$^{3+}$ ions and the B sites by Fe$^{2+}$ and Ni$^{2+}$ ions. Ni-Zn ferrite has a mixed spinel structure in which the A sites are occupied by Zn$^{2+}$ and Fe$^{3+}$ and the B sites by Ni$^{2+}$ and Fe$^{2+}$ ions [6-8]. Several approaches have been exploited to obtain more usable magnetic materials, including adjusting the substitution ions and ratio through the use of various synthesis methods. One of the advantages of using the sol-gel method is that a lower annealing temperature can be used to enable the growth of smaller grained powders. Thus, the sol-gel method can provide a multi-component oxide with a homogeneous composition, and it has been employed to prepare many high purity oxide powders, including some products with spinel-type structures [9, 10]. Recently we also studied nickel substituted effects on Co, Mn, MnZn ferrites synthesized by sol-gel method [11, 12]. In this study, the sol-gel method is used to synthesize the magnetic and nonmagnetic ion substituted manganese ferrites. The cobalt-, zinc-, and nickel-zinc-substituted nano-size manganese ferrite powders - MnFe$_2$O$_4$, Mn$_{0.8}$Co$_{0.2}$Fe$_2$O$_4$, Mn$_{0.8}$Zn$_{0.2}$Fe$_2$O$_4$ and Mn$_{0.8}$Ni$_{0.2}$Fe$_2$O$_4$ - and their crystallographic and magnetic properties were compared via X-ray diffractometry (XRD), field emission scanning electron microscopy (FESEM), Mössbauer spectroscopy, and vibrating sample magnetometry (VSM).

2. Experiment

MnFe$_2$O$_4$, Mn$_{0.8}$Co$_{0.2}$Fe$_2$O$_4$, Mn$_{0.8}$Zn$_{0.2}$Fe$_2$O$_4$, and Mn$_{0.8}$Ni$_{0.2}$Zn$_{0.8}$Fe$_2$O$_4$ ferrite samples were synthesized using the sol-gel method. Measured amounts of Mn(NO$_3$)$_2$·H$_2$O, Zn(NO$_3$)$_2$·6H$_2$O, Ni(NO$_3$)$_2$·6H$_2$O, and Fe(NO$_3$)$_3$·9H$_2$O were first dissolved in 2-Methoxyethanol with an ultrasonic cleaner for 30-50 min. The solution was refluxed at 353 K for 12 h in order to gel, and was dried at 363 K in a dry oven for 24 h. The dried powder samples were ground and annealed at various temperatures for 6 h, and all heat-treatment processes were carried out in an N$_2$ atmosphere to prevent the oxidation of the anion ions. A large amount of N$_2$ gas flowed early in the annealing process to remove the oxygen inside of the quartz tube and to emit the gas from the dry powder. In order to verify the purity, all samples were analyzed using an X-ray diffractometer with Cukα (1.54 Å) radiation. The surface microstructure was observed using FESEM at room temperature, and the Mössbauer spectra of the powders were recorded with a $^{57}$Co source in a constant acceleration mode to identify the magnetic phase of the ferrite powders. The saturation magnetization and the coercivity were then determined via VSM.

3. Results and Discussion

Figure 1 shows the X-ray diffraction patterns of the MnFe$_2$O$_4$ ferrite powders annealed at various temperatures, and the main peaks of the MnFe$_2$O$_4$ ferrite powders annealed above 523 K indicate a typical spinel structure. An increase in the annealing temperature leads to a sharpening of the major peak, which indicates the growth of the particle size of the spinel powders and an improvement in crystallization. The X-ray diffraction patterns of the Mn$_{0.8}$Co$_{0.2}$Fe$_2$O$_4$, Mn$_{0.8}$Zn$_{0.2}$Fe$_2$O$_4$, and Mn$_{0.8}$Ni$_{0.2}$Zn$_{0.8}$Fe$_2$O$_4$ ferrite powders annealed at 773 K are shown in Fig. 2. The X-ray diffraction measurement shows that all peaks are consistent with those of typical spinel structures of ferrite powders, and no extra peaks corresponding to any secondary phase could be observed. The lattice constant of the MnFe$_2$O$_4$ ferrite powder annealed at 773 K is 0.848 nm. As shown in Table 1, with an increase

![X-ray diffraction patterns of MnFe$_2$O$_4$ ferrite powders](image)

Fig. 1. X-ray diffraction patterns of MnFe$_2$O$_4$ ferrite powders annealed at various temperature: (a) 473 K, (b) 523 K, (c) 673 K, and (d) 773 K.
In substitution, the lattice constant of the four ferrites decreases from 0.848 nm (for MnFe$_2$O$_4$), to 0.843 nm (for Mn$_{0.8}$Co$_{0.2}$Fe$_2$O$_4$), to 0.847 nm (for Mn$_{0.8}$Zn$_{0.2}$Fe$_2$O$_4$), and to 0.841 nm (for Mn$_{0.8}$Ni$_{0.1}$Zn$_{0.1}$Fe$_2$O$_4$). This can be explained using Vegard's law [13], which states that larger Mn$^{2+}$ (0.091 nm) ions are substituted by smaller Co$^{2+}$ (0.072 nm), Ni$^{2+}$ (0.069 nm) and Zn$^{2+}$ (0.082 nm) ions, leading to a decrease in the lattice constants. The size of the particles was then determined from the broadening in the diffraction peak by using the Scherrer equation [14],

$$t = (0.9\lambda)/(B \cos \theta_B),$$

where $\lambda$ represent the X-ray wavelength, $B$ is the half width of the (311) peak, and $\theta_B$ is the angle of the (311) peak. The particle size of the

**Table 1.** Lattice constant and particle size of MnFe$_2$O$_4$, Mn$_{0.8}$Co$_{0.2}$Fe$_2$O$_4$, Mn$_{0.8}$Zn$_{0.2}$Fe$_2$O$_4$, and Mn$_{0.8}$Ni$_{0.1}$Zn$_{0.1}$Fe$_2$O$_4$ ferrite powders annealed at 773 K.
Mn$_{0.8}$Zn$_{0.2}$Fe$_2$O$_4$ ferrite powders has been reported to increase with an increase in the annealing temperature from 20.7 nm (523 K) to 45.7 nm (673 K), and 76.3 nm (773 K) [15]. As shown in Table 1, the size of the particle of samples annealed at 773 K is larger than that of pure MnFe$_2$O$_4$ (25.0 nm), such as with 40.0 nm for Mn$_{0.8}$Co$_{0.2}$Fe$_2$O$_4$, 76.3 nm for Mn$_{0.8}$Zn$_{0.2}$Fe$_2$O$_4$, and 90.9 nm for Mn$_{0.8}$Ni$_{0.2}$Zn$_{0.1}$Fe$_2$O$_4$ ferrite powders. This increase leads to a broadening of the major X-ray diffraction peak, that is, a growth in the smaller particle size of our spinel powders as well as an improved crystallization. All this also suggests that the manganese, manganese-cobalt, manganese-zinc and manganese-nickel-zinc ferrite powders synthesized via the sol-gel method have particle sizes ranging from 25.0 nm to 90.9 nm, which are smaller when compare to those of powders obtained using ceramic and wet chemical methods. As shown in Fig. 3, the shape of the grains of the ferrites can be confirmed via FESEM with 100,000 times magnification. All samples have nano-size grains of a nearly homogeneous size, and the grain size increases with the cobalt, zinc, and nickel-zinc substitution.

The Mössbauer spectra measured at room temperature for the MnFe$_2$O$_4$ powder annealed at 523 K, as shown in Fig. 4, is attributed to its paramagnetic behavior. This comes from having a small particle size, and superparamagnetic properties were confirmed with the low temperature Mössbauer spectra. The spectrum slowly changed from doublets at 180 K to Zeeman sextets below 50 K. Figure 5 shows the Mössbauer spectra that were measured at room temperature for MnFe$_2$O$_4$, Mn$_{0.5}$Co$_{0.5}$Fe$_2$O$_4$, Mn$_{0.8}$Zn$_{0.2}$Fe$_2$O$_4$ and Mn$_{0.8}$Ni$_{0.2}$Zn$_{0.1}$Fe$_2$O$_4$ ferrite powders annealed at 773 K. The spectra for MnFe$_2$O$_4$, Mn$_{0.8}$Co$_{0.2}$Fe$_2$O$_4$, and Mn$_{0.8}$Zn$_{0.2}$Fe$_2$O$_4$ are fitted with two six-line subspectra, and these are assigned to the tetrahedral A site and octahedral B sites of a typical spinel crystal structure. As shown in Fig. 5 (d) the Mössbauer spectrum for Mn$_{0.8}$Ni$_{0.2}$Zn$_{0.1}$Fe$_2$O$_4$ is fitted with two sextets and one doublet. The Mössbauer absorption spectra can be explained to be the result of a variation in the magnetic phase that is dependent on the particle sizes. As shown for Mn$_{1-x}$Zn$_x$Ni$_x$Fe$_2$O$_4$ ferrite powders [14, 15], the doublet originates from the small particle size, and superparamagnetic properties are confirmed with the low-temperature Mössbauer spectra. As shown in Table 2, the values of the quadrupole splitting (QS) and isomer shift (IS) of the A and B sites exhibited a small change with the cobalt, zinc, and nickel-zinc substitution. However, the values of the magnetic hyperfine fields ($H_{hf}$) of the cobalt-substituted sample increased some in the A and B sites, while the values of the magnetic hyperfine fields of zinc and nickel-zinc substituted samples decreased in the A and B sites. This variation in the values of the magnetic hyperfine fields indicates that the A-O-B superexchange

</table>
interaction is strengthened with cobalt substitution in Mn$_{0.8}$Co$_{0.2}$Fe$_4$O$_{12}$, but those of the A-O-B superexchange interaction are weakened with the zinc and nickel-zinc substitution in Mn$_{0.8}$Zn$_{0.2}$Fe$_4$O$_{12}$ and Mn$_{0.8}$Ni$_{0.1}$Zn$_{0.1}$Fe$_4$O$_{12}$. The variation in the A-O-B superexchange can also be explained through the use of a cation distribution. The cation distribution depends on many factors, such as the temperature, pressure, and composition [18, 19], as well as on the preparation method of compound. The Mössbauer absorption area ratio of the A and B sites, and the occupation preference sites for the substituted ions in a spinel structure, can both be used to determine the cation distribution of MnFe$_2$O$_4$, Mn$_{0.8}$Co$_{0.2}$Fe$_4$O$_{12}$, Mn$_{0.8}$Zn$_{0.2}$Fe$_4$O$_{12}$, and Mn$_{0.8}$Ni$_{0.1}$Zn$_{0.1}$Fe$_4$O$_{12}$ as:

(Mn$_{0.6}$Fe$_{0.4}$)$\cdot$[Mn$_{0.48}$Fe$_{1.52}$]O$_4$,
(Mn$_{0.33}$Fe$_{0.67}$)$\cdot$[Mn$_{0.42}$Co$_{0.20}$Fe$_{0.38}$]O$_4$,
(Zn$_{0.20}$Mn$_{0.20}$Fe$_{0.50}$)$\cdot$[Mn$_{0.55}$Fe$_{0.45}$]O$_4$,
(Mn$_{0.67}$Zn$_{0.13}$Fe$_{0.20}$)$\cdot$[Mn$_{0.19}$Ni$_{0.10}$Fe$_{0.71}$]O$_4$.

This cation distribution equation is used to explain the superexchange interaction that is stronger with the cobalt substitution. An increase in cobalt ions results in a higher magnetic moment for the Fe$^{3+}$ ions (5 $\mu_B$) at the A sites, so the A-O-B superexchange becomes stronger in Mn$_{0.8}$Co$_{0.2}$Fe$_4$O$_{12}$. Meanwhile, an increase in Zn$^{2+}$ (0 $\mu_B$) and Ni$^{2+}$ (2 $\mu_B$) ions results in a lower magnetic moment at the A sites, so the A-O-B superexchange becomes weaker in Mn$_{0.8}$Zn$_{0.2}$Fe$_4$O$_{12}$, and Mn$_{0.8}$Ni$_{0.1}$Zn$_{0.1}$Fe$_4$O$_{12}$.

The magnetic properties of the MnFe$_2$O$_4$, Mn$_{0.8}$Co$_{0.2}$Fe$_4$O$_{12}$, Mn$_{0.8}$Zn$_{0.2}$Fe$_4$O$_{12}$, and Mn$_{0.8}$Ni$_{0.1}$Zn$_{0.1}$Fe$_4$O$_{12}$ ferrite powders can be determined at room temperature via VSM. Figure 6 shows the hysteresis curves of the samples, revealing a typical soft ferrite pattern, and it shows the saturation magnetization and coercivity of the MnFe$_2$O$_4$, Mn$_{0.8}$Co$_{0.2}$-Fe$_4$O$_{12}$, Mn$_{0.8}$Zn$_{0.2}$Fe$_4$O$_{12}$ and Mn$_{0.8}$Ni$_{0.1}$Zn$_{0.1}$Fe$_4$O$_{12}$ ferrite powders annealed at 773 K. Relative to the saturation magnetization and coercivity of pure MnFe$_2$O$_4$, the Co-substituted manganese ferrite powder, Mn$_{0.8}$Co$_{0.2}$Fe$_4$O$_{12}$, were larger, and the Zn and Ni-Zn substituted manganese ferrite powders, Mn$_{0.8}$Zn$_{0.2}$Fe$_4$O$_{12}$ and Mn$_{0.8}$Ni$_{0.1}$Zn$_{0.1}$Fe$_4$O$_{12}$, were smaller. These variations could thus be explained by using the cation distribution equations, particle sizes and magnetic moments of the substituted ions Mn$_{1.75}$Co$_{0.25}$Fe$_4$O$_{12}$ ferrite powders have been reported to have a saturation magnetization that increased drastically with an increase in cobalt concentration up to x = 0.6 and then a decreased thereafter, and the coercivity increased up to x = 0.8 and then decreased [15]. The larger saturation magnetization 67.65 emu/g in Mn$_{0.8}$Co$_{0.2}$Fe$_4$O$_{12}$ than that 53.85 emu/g in MnFe$_2$O$_4$ could be qualitatively explained using the cation distribution equation and particle size effect of the substituted Co ions. The Mössbauer absorption area in Mn$_{0.8}$Co$_{0.2}$Fe$_4$O$_{12}$ shows that the octahedral Fe and Mn ions decreased as the Co ions increased. The substitution of the Mn$^{2+}$ (5 $\mu_B$) and Fe$^{3+}$ (5 $\mu_B$) with a greater magnetic moment ions by the Co$^{2+}$ (3 $\mu_B$) with lesser magnetic moment ions could be expected to reduce the saturation magnetization. Therefore, the results of this work do not support this explanation. However, the XRD and SEM
results show that the particles increased in size with cobalt ion substitution, and this could have led to an increase in the saturation magnetization and coercivity. Similar results were obtained in Mn-Co thin film and CoO.3Mn0.7Fe2O4 nanoparticles [20, 21]. In the Mn0.8Zn0.2Fe2O4 ferrite powder, the value of the saturation magnetization 41.06 emu/g is smaller than that of pure MnFe2O4, and this decrease can be explained by the substitution of nonmagnetic Zn2+ (0 μB) ions substituted for Mn2+ (5 μB) ions with a larger magnetic moment. From the cation distribution equation, the Fe3+ (5 μB) distributed between the A and B sites remain almost unchanged, so the saturation magnetization value of the Mn0.8Zn0.2Fe2O4 ferrite should smaller. The coercivity value also decreases rapidly from 124.6 Oe in MnFe2O4 to 92.2 Oe in Mn0.8Zn0.2Fe2O4 ferrite powder as the zinc substitution. The coercivity in polycrystalline ferrites is well known to be strongly dependent on the magneto crystalline anisotropy constant and the grain size. In the Mn0.8Zn0.2Fe2O4 ferrite powder, the grain size does not change abruptly, so the main effect on the coercivity decrease may be a decrease in the magneto crystalline anisotropy constant for Zn2+, with respect to that of Mn2+. This result indicates that, the Mn0.8Zn0.2Fe2O4 ferrite shows a lower saturation magnetization and coercivity than pure MnFe2O4. In the Mn0.8Ni0.2Zn0.4Fe2O4 ferrite powder, the saturation magnetization is somewhat smaller (36.55 emu/g) than that of pure Fe2O4 (53.85 emu/g). This variation could be qualitatively explained by the superparamagnetic phase that is dependent on the particle size and the magnetic moment of the substituted Ni and Zn ions. The Mössbauer absorption area indicates that the doublet is a result of the superparamagnetic phase in Mn0.8Ni0.2Zn0.4Fe2O4, and this could produce high values for the saturation magnetization. However the replacement of ions with a larger magnetic moment (Fe3+ = 5 μB, Mn2+ = 5 μB) by ions with a smaller magnetic moment (Ni2+ = 3 μB, Zn2+ = 0 μB) could produce low values for the saturation magnetization. As a result of these two effects, the saturation magnetization decreases slightly with Ni and Zn substitution [19], and the coercivity (105.8 Oe) of the Mn0.8Ni0.2Zn0.4Fe2O4 ferrite powder is smaller than that of pure MnFe2O4, which could also be related to the particle size [17, 19]. The superparamagnetic phase resulting from the smaller particle size changed to a ferrimagnetic phase, as confirmed by the Mössbauer spectra. These results reflect a relatively low coercivity when compared to the value for MnFe2O4. Similar results were obtained for the Mn0.8Zn0.2Fe2O4 and Mn0.8Ni0.2Fe2O4 ferrite powders [15, 22].

4. Conclusion

Cobalt-, zinc-, and nickel-zinc-substituted nano-size manganese ferrite powders, MnFe2O4, Mn0.8Co0.2Fe2O4, Mn0.3Zn0.7Fe2O4 and Mn0.8Ni0.2Zn0.4Fe2O4 were fabricated via the sol-gel method, and their crystallographic and magnetic properties were compared. The MnFe2O4 ferrite powder annealed at temperatures above 523 K exhibited the presence of a spinel structure, and the particle size increased as the annealing temperature increased. All ferrite samples annealed at 773 K showed a single spinel structure, with lattice constants that decreased and particle size that increased with the substitution of MnFe2O4 ferrites with Co, Zn, and Ni-Zn. The Mössbauer spectrum of the MnFe2O4 ferrite powder annealed at 523 K showed only a doublet due to its superparamagnetic phase. The Mössbauer spectra of MnFe2O4, Mn0.8Co0.2Fe2O4, Mn0.8Zn0.2Fe2O4 ferrite powders annealed at 773 K could be fitted as the superposition of two Zeeman sextets due to the A and B sites of the Fe3+ ions. However, the Mössbauer spectrum of Mn0.8Ni0.2Zn0.4Fe2O4 consisted of two Zeeman sextets and one quadrupole doublet resulting from the ferrimagnetic and paramagnetic behavior. The area ratio of the Mössbauer spectra can be used to decide the cation distribution of MnFe2O4, Mn0.8Co0.2Fe2O4, Mn0.8Zn0.2Fe2O4 and Mn0.8Ni0.2Zn0.4Fe2O4 as (Mn0.5Fe0.4Mn0.5Fe0.4)[Mn0.42Fe1.52]O4, (Mn0.35Fe0.65)[Mn0.42Co0.2Fe1.58]O4, (Zn0.2Mn0.55Fe0.42)O4, (Mn0.35Fe0.42)[Mn0.19Ni0.10Fe1.71]O4.

We also explained the variation in the Mössbauer parameters using this cation distribution equation, superexchange interaction and particle size. Relative to pure MnFe2O4, the saturation magnetizations and coercivities are larger in the Mn0.8Co0.2Fe2O4 and are smaller in Mn0.8Zn0.2Fe2O4 and Mn0.8Ni0.2Zn0.4Fe2O4. These variations could be explained by using the site distribution equations, particle sizes and magnetic moments of the substituted ions.
